

Trend Following, Leveraged Re-Entry, and Volatility Decay

S&P 500 total return. One signal only: the 200-day moving average (the daily equivalent of Faber's 10-month rule). Tested as far back as the data allows.

Data. Total return throughout. Monthly S&P 500 total return back to 1901 (Shiller) for the Faber replication; a daily total return series from 1928 for everything else — real $\wedge\text{SP500TR}$ from 1988, and before that $\wedge\text{GSPC}$ price plus the Shiller dividend yield (this reconstruction tracks the real series with 0.50%/yr error and 0.9996 correlation over 1988–2026). Cash and the financing of leverage use **real T-bill rates** throughout: $\wedge\text{IRX}$ (13-week T-bill) from 1960, and the Ken French / Ibbotson **1-month T-bill** (monthly) before that, back to 1926 — so the risk-free is **real** across the entire 1928+ daily sample ($\approx 0\%$ in the 1930s–40s, $\sim 1\text{--}3\%$ in the 1950s, $\sim 3.2\%$ mean). The trend signal is lagged one day, so nothing uses information we could not have had.

Data provenance — what is real. Every return and every cash rate in this study is *real, physical* market data, not an assumption:

- **Daily total return** — real $\wedge\text{SP500TR}$ from 1988; before that, **real** $\wedge\text{GSPC}$ price returns plus the **real** Shiller dividend yield (a reconstruction of total return from two real series, validated against $\wedge\text{SP500TR}$ at 0.50%/yr tracking error and 0.9996 correlation over 1988–2026). The pipeline **refuses to run** on the synthetic offline-fallback series.
- **Monthly total return** (Faber replication) — real Shiller price + dividends.
- **T-bill / cash** — real $\wedge\text{IRX}$ (1960+) and real Ken French / Ibbotson 1-month bill (1926+). The *only* span with no free real short-rate data is **1901–1926** (touched solely by the monthly replication); there we apply the **average of the real T-bill series ($\approx 3.3\%/yr$)**, not an arbitrary constant.
- **The one explicit model** (not data) is the cost set in \$2 (expense, financing spread over the real T-bill, turnover); every result is also available *gross*.

How the ratios are computed (all from *daily* returns, then annualized):

- **CAGR** — geometric: the constant yearly rate that turns the start wealth into the end wealth. "Grew \$1 to" is the literal end value of \$1.
- **Volatility** — annualized standard deviation of daily returns ($\times \sqrt{252}$).
- **Sharpe** = annualized **mean** daily excess return over the T-bill $\div$ volatility. It uses the *arithmetic mean*, **not** the CAGR. For high-volatility strategies the arithmetic mean sits far above the CAGR (by $\approx \frac{1}{2}\text{-vol}^2$, the variance drag), so Sharpe will **not** equal $(\text{CAGR} - \text{rf})/\text{vol}$ — e.g. the 4x-above rule's arithmetic mean is $\sim 35\%$ vs a 20.7% CAGR, giving Sharpe ≈ 0.56 , not $(20.7\% - 3\%)/52\% \approx 0.34$. This is the standard definition and is correct; the volatility column lets you check it directly from the arithmetic mean.
- **Sortino** — same as Sharpe but the denominator counts only downside deviation (shortfalls below zero, averaged over *all* days).
- **Calmar** = $\text{CAGR} \div |\text{max drawdown}|$.
- **Information ratio (IR vs S&P)** = annualized mean of (strategy – S&P buy-&-hold) daily return $\div$ its standard deviation (the tracking error). It is undefined for buy-and-hold itself (it *is* the benchmark).

1. Buy & hold vs the Faber moving-average rule

The rule: hold the S&P 500 while it is **above** its moving average; move to **cash** while it is **below**. Faber uses the 10-month SMA on monthly data; we use that, then its daily twin (the 200-day SMA).

Monthly, 1901–2026 (Faber's exact setup):

	S&P 500 buy & hold	10-month timing → cash
CAGR	9.95%	10.99%
Volatility	15.4%	10.9%
Sharpe	0.49	0.72
Max drawdown	–81.8%	–47.5%

(Faber's published drawdowns are $-83.66\% \rightarrow -42.24\%$; we reproduce the same qualitative halving — small differences come from extending the sample to 2026 and using real, near-zero 1930s–40s cash rates.)

Daily, 200-day SMA, 1928–2026:

	Buy & Hold 1×	MA200 → Cash
CAGR	10.14%	11.01%
Volatility	18.9%	12.6%
Sharpe	0.43	0.63
Sortino	0.62	0.90
Max drawdown	−83.9%	−46.4%
Calmar	0.12	0.24

The moving-average rule keeps essentially all of the return while cutting volatility by a third and halving the worst drawdown, so its Sharpe, Sortino and Calmar are all much higher. The 200-day MA adds clear risk-adjusted value.

2. Leverage returns

A daily **L×** leveraged return is simply that day's S&P 500 total return multiplied by L, and then compounded day by day:

$$\text{leveraged_return}[t] = L \times \text{sp500_return}[t] \quad (\text{before fees / financing})$$

For example, the 2× series is just the daily S&P total return × 2, compounded. Borrowed money costs the financing rate, and leveraged funds charge a fee (~0.9%/ yr); both are included below.

Holding **constant** daily leverage on the index, net of costs:

	CAGR	Grew \$1 to
1× (buy & hold)	10.14%	\$13,021
Always 1.5×	10.93%	\$25,037
Always 2×	11.59%	\$49,549
Always 3×	10.09%	\$12,094
Always 4×	4.20%	\$54

Constant leverage helps a little up to ~2×, then **runs out of road**: constant 3× only matches buy & hold and constant 4× collapses to \$54 (CAGR 4.2%) — across a full century (including the 1929, 1987 and 2008 crashes) the volatility drag and deep drawdowns overwhelm the extra exposure. Section 6 shows that *switching* the leverage with the trend fixes this.

3. Volatility decay, and buying leverage at the lows

Volatility decay. A +10% day followed by a −10% day:

	1×	2×	3×
Two-day return	−1.0%	−4.0%	−9.0%

The market round-trips to roughly flat, but leverage loses — and the loss grows with the *square* of leverage. The annual penalty is $\approx \frac{1}{2} \cdot L^2 \cdot \sigma^2$: at 20% volatility, ~2%/yr for 1×, **8%/yr for 2×**, **18%/yr for 3×**.

Volatility decay: the **SAME** daily leverage helps or hurts depending on the path

But decay only bites in choppy/falling markets. In a one-directional rally — like the rebound off a market bottom —

leverage amplifies the gain. Forward **1-year** total return if you had bought at the exact low:

Bottom	1×	1.5×	2×	3×	4×
GFC (2009-03-09)	+72%	+122%	+182%	+339%	+550%
2018 Q4 (2018-12-24)	+40%	+64%	+92%	+159%	+244%
COVID (2020-03-23)	+78%	+132%	+198%	+372%	+605%
2025 tariff selloff (2025-04-08)	+39%	+61%	+87%	+146%	+216%

Leverage can work strongly in your favour **if you time it** — buying into the recovery off a low. (The low, of course, is only obvious in hindsight.)

4. The leverage at which the total return goes flat

Think of the asset as Brownian motion with an annual **drift** μ (the arithmetic mean return) and **volatility** σ . The compound (geometric) growth of $L\times$ daily leverage is $g(L) = L \cdot \mu - \frac{1}{2} \cdot L^2 \cdot \sigma^2$. Setting it to zero gives the leverage at which volatility decay exactly cancels the drift, so the **total return is flat (0%)**:

$$L_{\text{zero}} = 2 \cdot \mu / \sigma^2$$

Below it, leverage still grows; above it, leverage **loses money**. The map below plots L_{zero} for every combination of drift and volatility. For the S&P over the **last 10 years** (mean return $\sim 15.9\%$, volatility $\sim 18.1\%$) the flat point is $\approx 10\times$ — so a hypothetical "10 $\times$ S&P" would have gone essentially nowhere despite a strong decade, while higher still would have bled toward zero.

(For reference, the leverage that merely *ties* 1× buy & hold is lower — $\approx 3.1\times$ for the S&P — and the growth-maximising level is $\approx 2\times$; see [charts/F3_breakeven_leverage_map.png](#) and [charts/F3_optimal_leverage_curve.png](#).)

5. The switching strategy: leverage the uptrend

Use the 200-day MA to switch between leveraged and ordinary exposure: **hold L× leverage while the market is ABOVE the MA** — the calm, rising regime where the one-directional gains seen in §3 happen — and drop back to plain 1× while it is below. Each strategy is shown over the full history and the last 50 / 30 / 15 years (net of costs; the volatility column lets you reproduce the Sharpe):

Full history (1928+):

Strategy	Grew \$1 to	CAGR	Vol	Sharpe	Sortino	Calmar	Max DD	IR vs S&P
Buy & Hold 1x	\$13,021	10.1%	18.9%	0.43	0.62	0.12	-83.9%	—

Lev 4x above MA	\$216.0	19.7%	50.6%	0.57	0.79	0.23	-86.1%	0.53

Last 15 years:

Strategy	Grew \$1 to	CAGR	Vol	Sharpe	Sortino	Calmar	Max DD	IR vs S&P
Buy & Hold 1x	\$7.68	14.6%	17.3%	0.79	1.11	0.43	-33.8%	—
MA200 -> Cash	\$4.68	10.9%	11.8%	0.81	1.11	0.61	-18.0%	-0.32
Lev 1.5x above MA	\$11.5	17.8%	21.7%	0.79	1.10	0.44	-40.1%	0.61
Lev 2x above MA	\$18.6	21.6%	26.7%	0.81	1.12	0.47	-45.8%	0.68
Lev 3x above MA	\$41.1	28.2%	37.5%	0.81	1.12	0.50	-56.0%	0.72
Lev 4x above MA	\$73.2	33.2%	48.7%	0.81	1.10	0.52	-64.5%	0.73

Leverage the uptrend (above MA, 1x below) -- full (1928+)

Leverage the uptrend (above MA, 1x below) -- last 50y

Leverage the uptrend (above MA, 1x below) -- last 30y

Reading the table. Leveraging the uptrend beats buy & hold on CAGR, Sortino and Calmar at every horizon, and matches its Sharpe in recent windows (last 15y: Sharpe ≈ 0.81 at 2–3 $\times$, same as buy & hold, but far higher CAGR). The **information ratio vs the S&P is strongly positive and rises with leverage** (0.47 $\rightarrow$ 0.57 over the full century, up to 0.73 over the last 15 years), so the leverage is adding genuine benchmark-relative return — note that plain MA $\rightarrow$ cash has a **negative** IR in recent windows (–0.11 to –0.32): it has *lagged* the index since the bull began. The cost is drawdown, which deepens with leverage (–86% at 1.5 $\times$ to –99% at 4 $\times$ over the full century).

6. Does the MA switch add value over just holding leverage?

Is the switching doing the work, or could you just hold constant leverage? Holding each level *constantly* versus only **above the MA** (the switched rows are bold), 1928–2026:

Strategy	Grew \$1 to	CAGR	Vol	Sharpe	Sortino	Max DD	IR vs S&P
Buy & Hold 1x	\$13,021	10.1%	18.9%	0.43	0.62	-83.9%	—
Always 1.5x (constant)	\$25,037	10.9%	28.4%	0.39	0.56	-94.9%	0.31
Lev 1.5x above MA	\$70,781	12.2%	23.6%	0.47	0.66	-85.7%	0.47
Always 2x (constant)	\$49,549	11.6%	37.8%	0.40	0.56	-98.5%	0.36
Lev 2x above MA	\$655,939	14.8%	28.9%	0.51	0.72	-89.0%	0.53
Always 3x (constant)	\$12,094	10.1%	56.8%	0.40	0.57	-99.9%	0.38
Lev 3x above MA	\$17,050,454	18.7%	40.4%	0.55	0.77	-95.5%	0.56
Always 4x (constant)	\$54	4.2%	75.7%	0.40	0.57	-100.0%	0.39
Lev 4x above MA	\$87,028,073	20.7%	52.5%	0.56	0.80	-98.8%	0.57

The chart below zooms into the **last 10 years** so the dashed (constant) and solid (switched) lines are clearly distinguishable; the table above is the full history.

The switch adds enormous value at every level: the MA-switched version has higher CAGR, Sharpe **and** a shallower drawdown than holding the same leverage all the time. Constant leverage runs out of road as it rises — constant 3× merely *matches* buy & hold (\$12,094 vs \$13,021) despite triple the volatility, and constant 4× **collapses to \$54** (CAGR 4.2%, a –100% interim drawdown). The switched versions grow \$1 to \$656k (2×) and **\$87 million** (4×). Constant leverage piles on volatility (Sharpe stuck near 0.40) for little extra compound return; the trend filter is what makes leverage pay.

7. Leverage → cash: sidestep the downturns

Instead of dropping to plain 1× below the MA, go all the way to **cash**. Over full / 50 / 30 / 15-year horizons (net):

Lev 4x above->cash	\$43.0	28.6%	47.0%	0.74	1.01	0.45	-63.0%	0.57

Leverage above the MA, cash below -- full (1928+)

Leverage above the MA, cash below -- last 50y

Leverage above the MA, cash below -- last 30y

Going to cash (not 1x) below the trend **shallows the drawdown** versus leverage-to-1x (2x above→cash: -75% over the full century, and only -37% / -47% over the last 15 / 30 years, against the leverage-to-1x -46% / -63%). The price is that in the recent bull its Sharpe (≈ 0.73 over 15 years) dips *below* buy & hold's (0.79), because the cash periods missed dips that quickly recovered.

8. A three-tier rule: leverage → S&P → cash

This version makes the **fast (3-month) MA the cash trigger** — the idea being that bear markets are short and sharp, so getting to cash *fast* on a big down move matters more than waiting for the slow 200-day to break. The three states: **leverage** above *both* MAs (strong, calm uptrend); **cash** the moment price falls below the 3-month MA (a sharp drop — get out); **plain 1x S&P** while back above the 3-month MA but still below the 200-day (recovering off a low). Over full / 50 / 30 / 15-year horizons (net):

3-tier 3x	\$4.08	9.8%	30.2%	0.41	0.56	0.21	-47.2%	-0.05
3-tier 4x	\$4.39	10.4%	40.1%	0.41	0.56	0.18	-59.3%	0.09

This is the clearest illustration of the trend-following trade-off in the whole study. Exiting to cash the instant price slips below the 3-month MA *does* keep the worst-case drawdowns shallow (3-tier 1.5x: only –28% over the last 15 years, versus buy & hold's –34%). But the same hair-trigger **whipsaws badly in choppy bulls**: over the last 15 years the rule grew \$1 to only **\$2.7–\$4.4 at Sharpe 0.41** — well behind buy & hold (\$7.68) and even plain MA→cash — because it bailed to cash on every minor dip and then missed the snap-back. Its full-century Sharpe (~0.50–0.52) also sits *below* the gentler leverage→cash rule (~0.57). Fast cash exits are a powerful hedge against genuinely sharp, sustained bears, but in markets where most dips recover quickly they cost more in missed upside than they save in avoided losses.

An interesting cross-cutting result. The variants rank differently by *era*. Over the full 1928+ history (which contains real, sustained bears), the gentler **leverage→cash** rule has the best risk-adjusted numbers of the leveraged variants (Sharpe ~0.57–0.58), while the hair-trigger 3-tier whipsaws (~0.50–0.52). Over the **last 15 years** (a bull with only fast, V-shaped dips), the *least* defensive rule — straight leverage-above-MA — wins outright (Sharpe ~0.81, matching buy & hold but with far higher growth), because every moment in cash or 1x was a moment out of a recovering market. There is no single best variant: the right amount of de-risking depends entirely on whether bear markets persist or snap back.

Educational research only — not investment advice. Reproduce with `python run_faber_leverage.py`; figures are in `charts/`, numbers in `results/`.
